Speech rate mediated compensation for assimilation in spoken word recognition

Spoken word recognition; Speech rate; Visual world paradigm

The role of speech rate has received relatively little attention in spoken word recognition, although speech production studies have shown that it can alter patterns of coarticulation and assimilation (e.g. [1]). Previous studies have shown that listeners can compensate for coarticulation, perceiving identical sounds differently in different contexts (e.g. [4]). In addition, listeners may also compensate for assimilation ([3]), a phenomenon observable in sentences like “A quick run picks you up.” Here, run may sound like rum when /n/ becomes assimilated to /m/ due to the influence of /p/. We wanted to test whether listeners’ processing of (potentially) assimilated sounds is sensitive to speech rate. Given that faster speech rates are associated with more coarticulation, run may be more acoustically similar to rum at faster speech rates than slower speech rates. Therefore, when identical lexically-ambiguous forms resulting from coronal assimilation are presented to listeners, we predict that these forms should be (i) more likely to be interpreted as the unassimilated form (e.g. run) when embedded in fast speech rates but (ii) more likely to be interpreted as the assimilated form (e.g. rum) when embedded in slower rates.

To test whether speech rate influences the interpretation of lexically-ambiguous forms, we conducted a visual-world eye-tracking study. Target sequences (noun+verb) were spliced into carrier phrases with different speech rates (fast/medium/slow, ex.1). The critical noun+verb sequences had two different coarticulation overlap patterns between the noun and verb (less overlap=more /n/-like vs. more overlap=more /m/-like), elicited with different prosodic contexts. Thus, we had a 3x2 design (36 targets, 50 fillers). To avoid neighborhood-density or plausibility confounds, critical nouns were nonwords: Participants were taught the nonwords were the names of aliens. Participants (n=24) listened to sentences and saw displays showing different aliens, two of which were the critical images (e.g. pictures of aliens called Vone and Vome). They were instructed to click on the alien mentioned.

Results: Eye-movement patterns show speech rate x overlap interaction 100-300ms and 400-600ms after alien-name onset (p<.05). More specifically, in the ‘more overlap’ conditions (more /m/-like), participants are more likely to look to the unassimilated form (e.g. Vone) in the fast and medium speech-rate conditions, but in the slow speech-rate condition, there are more looks to the assimilated form (e.g. Vome). In the ‘less overlap’ conditions (more /n/-like), participants tend to look at the unassimilated form in the slow speech-rate condition instead.

Conclusions: Even with identical acoustic materials, listeners’ online interpretations of ambiguous words are influenced by the speech rate of the surrounding carrier sentence. These findings are consistent with work on speech rate and perception of function words ([2]), as well as research showing that listeners are sensitive to sub-phonemic variation (e.g. [5]). While existing theories may accommodate our findings in different ways, the general point that emerges from our study is the importance of including speech rate in models of spoken recognition.

(1) Carrier phrase part 1 | Target N+V sequence | Carrier phrase part 2
---|---|---
Every time the waiter brings out a strawberry cheesecake from the kitchen, Vone peeks or Vome peeks | Less or more overlap | Fast, medium, or slow
Fast, medium, or slow | to see if he can steal a piece.
